## SUMMARY

Estimates are given of the magnitudes, epicentres and origin times of 76 explosions fired by France at the Tuamotu Archipelago in the South Pacific for which time and amplitude data are published in the bulletins of the International Seismological Centre (ISC). Most of the explosions took place at Mururoa but 5 seem to have been fired at the neighbouring island of Fangataufa; Mururoa and Fangataufa being about 50 km apart. The epicentres and origin times are estimated using the joint epicentre method. The epicentres are estimated relative to that of the explosion of the 25 July 1979. The epicentre of this explosion was chosen so that the pattern of epicentres in the vicinity of Mururoa fits centrally over the island.

The magnitudes are determined using a joint maximum-likelihood method. With this method allowance is made for the detection threshold of the stations reporting $P$ amplitudes. If such allowance is not made the estimates will usually be biased high with the bias increasing as magnitude decreases. However, for the Tuamotu explosions systematic differences between the maximumlikelihood estimates of magnitude and the ISC estimates are small and are negligible above $\mathrm{m}_{\mathrm{b}} 5.5$.

The joint methods of epicentre and magnitude estimation also produce estimates of station time and magnitude effects. These effects are listed for up to $\mathbf{5 8 2}$ stations.

## 1. INTRODUCTION

Marshall et al [1] give estimates of the body wave magnitudes, epicentres and origin times of some of the explosions carried out by France at the Mururoa atoll in the Tuamotu Archipelago in the South Pacific. The explosions are those that occurred between 1975 and 1985 for which data on onset time and amplitude are published in the bulletins of the International Seismological Centre (ISC). In this report we give similar estimates for the 76 explosions that took place in the South Pacific between 1968 and 1989 and which are reported in the ISC bulletins. Five of the explosions (which took place in 1968-71) were fired in the atmosphere (Bolt [2]); the remainder appear to have been fired underground. Most of the explosions took place at Mururoa but as shown by the analysis presented here 5 (including 2 atmospheric explosions) appear to have been fired at the neighbouring island of Fangataufa; Mururoa and Fangataufa being about 50 km apart.

In computing the epicentres and origin times we follow Marshall et al [1] and use the method of Joint Epicentre Determination (JED) of Douglas [3]. To estimate the magnitude, the joint maximum-likelihood method of Lilwall[4] and Lilwall and Neary [5] is used. The method has an advantage over the least squares method used by Marshall et al [1] in that allowance is made for the detection (or reporting) thresholds of the stations. If such allowance is not made the estimates are biased high with the bias increasing as magnitude decreases.

## 2. <br> EPICENTRE RELOCATIONS

The JED method was used to relocate the explosions using P \& PKP arrival times taken from ISC bulletins. Arrival time readings were weighted to allow for gross errors and for variation between stations in the quality of the arrival time measurements. The effect of gross errors is reduced using the method of uniform reduction (Jeffreys [6]). The method assumes that the errors in the observations are essentially normally distributed but that the distribution is modified by the
addition of a small uniform distribution due to gross errors. This modification to the distribution results in weights that progressively reduce the contribution of residuals as their deviation from the mode increases.

For stations that report sufficient explosions (here set at 10) the standard deviation of the residuals is calculated and used to weight the arrival times for the station. This technique permits the incorporation of a large body of PKP data which would normally be given zero weight because its variance is significantly greater than that of most P observations.

Two analyses were carried out, one using all the data, the other using only data for what appear to be the five explosions at Fangataufa. Consider first the analysis that uses data from all 76 explosions. To fix the overall location of the group, one of the epicentres was restrained to a predetermined value. The restrained epicentre chosen is that for the explosion on 25 July 1979, one of the largest and most widely recorded of the explosions. No true epicentre for the explosion has been published and so the location must be fixed using other evidence. The strategy used by Marshall et al[1] was to shift the restrained epicentre until the overall pattern fitted centrally over Mururoa island. The epicentre used by Marshall et al [1] (21.88S, 138.94W) gives for the data they used, the minimum deviation of the median location from the lagoon centre (taken as 21.83S, 138.91W). Confidence in the restrained location is gained by the fact that the ISC location (21.86S, 139.0 W ) is roughly 6 km WNW of the chosen position, a bias similar to that expected when station travel time corrections are not used (Lilwall \& Underwood [7]). Here the epicentres have been determined relative to the same restrained epicentre as used by Marshall et al [1]. All depths are restrained to zero and the origin time of the 25 July 1979 explosion was restrained to the nearest exact minute (17:57:00). A total of 554 stations was used.

Figure 1(a) shows the ISC epicentres for all 76 explosions. Although the epicentres are clearly concentrated around Mururoa, many lie well out to sea and there is no obvious separate group of epicentres associated with Fangataufa. The JED results on the other hand (figure 1(b)) show clearly the separation of the epicentres into two groups: 5 in the vicinity of Fangataufa and most of the remainder on or near Mururoa. One other epicentre, that for the explosion of 27 October 1984 (at $22.064 \mathrm{~S}, 138.477 \mathrm{~W}$ which is SE of Mururoa) is somewhat closer to Fangataufa than to Mururoa and so may be another Fangataufa explosion. However, the uncertainty in the epicentral estimate is large, the confidence ellipse has semi-minor and semi-major axes of about 9 and 29 km respectively and the major axis is oriented NW-SE. Thus if the true epicentre is on one of the two islands it is more likely to be on Mururoa than Fangataufa. Consequently it is assumed here that the 27 October 1984 explosion was fired at Mururoa.

Figure 1(c) shows the results of the JED analysis of the five Fangataufa explosions. Here the epicentre of one of the explosions (that of 30 November 1988) has been restrained to the centre of the island $(22.233 \mathrm{~S}, 138.74 \mathrm{~W})$. Three of the epicentres (which are for the underground explosions) now form a very tight group which lie on or close to the island. The epicentres of the other two, which are atmospheric explosions, lie out to sea.

Table 1 gives the relocated epicentres, origin times and $95 \%$ confidence limits. In addition to the epicentres, the JED method gives estimates of the station time-terms. These are listed in table 2. Positive values, show that the signal was late relative to the time predicted from traveltime tables (here Jeffreys-Bullen) and conversely a negative value shows that the onset is early relative to the predicted time. If the time terms are to be used as corrections which when added to the observed time corrects for deviations from predicted times, then all the time terms should have their sign reversed.

Given $n$ explosions recorded at some or all of $q$ stations, then it is usually assumed that $m_{i j}$ the magnitude of the ith explosion recorded at the jth station can be written:

$$
m_{i j}=b_{i}+s_{j}+\varepsilon_{i j}
$$

where $b_{i}$ is the magnitude of explosion $i, s_{j}$ is a station term and $\varepsilon_{i j}$ is an error term. Following Gutenberg and Richter [8] the body wave magnitude at station $j$ for explosion $i$ is:

$$
m_{i j}=\log A_{i j} / T_{i j}+B\left(\Delta_{i j}\right)
$$

where $A_{i j}$ is the amplitude of the $P$ wave, $T_{i j}$ its predominant period, and $B\left(\Delta_{y}\right)$ the correction factor for the distance $\Delta_{i j}$ between explosion $i$ and station $j$. Usually $b_{i}$ and $s_{j}$ are estimated by least squares (see for example Douglas [9]) with the assumption that:

$$
\begin{equation*}
\sum_{j=1}^{\mathrm{paq}} \mathrm{~s}_{\mathrm{j}}=0 \tag{1}
\end{equation*}
$$

Such estimates are unbiased if the observed $\mathrm{m}_{\mathrm{ij}}$ are sampled randomly from a normal distribution. In practice however, the distribution of $m_{1 j}$ will not be normal. Below average amplitudes will tend to be under-reported because at some stations the amplitude will be so small it will not be detected or if detected will not be measured and reported to data centres. Magnitudes estimated by least squares will thus tend to be biased high.

Lilwall [4] and Lilwall and Neary [5] following Christoffersson [10] shows that unbiased estimates of magnitude (and station effects) can be obtained (given estimates of station threshold and the variance of the threshold) by using maximum-likelihood methods, again with the assumption given in (1). Using Lilwall's method, maximum-likelihood estimates of body wave magnitude $\left(m_{b}^{\text {Ma }}\right)$ have been determined for all the 76 explosions considered here.

From Christoffersson et al [10] the distribution of observed station magnitudes $m_{i j}$ can be written as:

$$
\begin{equation*}
P\left(m_{\mathrm{k}} \mid b_{i}, s_{j}, \sigma . .\right)=\frac{\phi\left(\frac{m_{3 j}-G_{j}}{\gamma_{i}}\right) \theta\left(\frac{m_{i j}-s_{j}-b_{i}}{\sigma}\right)}{\phi\left(\frac{s_{j}+b_{1}-G_{j}}{\sqrt{\left(\sigma^{2}+\gamma_{j}^{2}\right)}}\right)} \tag{2}
\end{equation*}
$$

(3) where $G_{j}=g_{j}+B\left(\Delta_{y}\right)$.
$\theta$ is the normal density function of variance $\sigma^{2}$ representing the distribution of "uncensored" values of $m_{i j} ; \phi$ the cumulative normal distribution; $g_{j}$ the mean (50\%) amplitude measurement threshold in terms of $\log \mathrm{A} / \mathrm{T}$ for station $\mathrm{j} ; \gamma_{j}^{2}$ the variance of the threshold assumed normally distributed about $g_{j}$. If the sources are close together equation 3 enables the main $\log A / T$ thresholds $g_{j}$ to be expressed in terms of magnitude thresholds $\mathrm{G}_{\mathrm{j}}$.

Estimates of $b_{i}, s_{j}$ and $\sigma$ can be determined by maximising the likelihood function resulting from the product over the observed values of $m_{i j}$ of terms given by equation 2 .

$$
\begin{equation*}
L\left(b_{i}, s_{j}, \sigma\right)=\prod_{\substack{\text { observed } \\ m_{l j}}}^{\Pi} P\left(m_{l j} \mid b_{i}, s_{j} \ldots\right) \tag{4}
\end{equation*}
$$

Maximisation being subject to the constraint given by equation 1.
Ideally station thresholds and the variance of the thresholds would be determined once for each station and then used for all time. However, station thresholds do change with time. Possible reasons for this might be increased noise levels due to the growth of industry in the vicinity of the station and changes in reporting procedures with some stations deciding to measure amplitudes on smaller signals than they had in the past. Estimates of station thresholds and variance covering the period 1982-1989 have been combined with those of Lilwall and Neary [5] to cover the whole period 1964-1989. The threshold and variances are estimated from the overall distribution of $\log$ A/T submitted to the ISC for each station using the method of Kelly and Lacoss [11]. As with the travel times the effects of gross errors in the amplitudes is reduced using weighting based on the method of uniform reduction (Jeffreys [6]). Examination of the distributions of observed amplitudes away from the mode suggests that the frequency of gross errors is 0.01 times the peak frequency.

For the amplitude analysis the explosions have been divided into three groups: (i) Mururoa underground; (ii) Fangataufa underground; and (iii) atmospherics. The JED results suggest that station time-terms are roughly constant for all the epicentres in the region. Thus, fixing an epicentre at Mururoa does not introduce any obvious systematic bias into the epicentres of the Fangataufa explosions when the epicentres of the explosions at the two islands are estimated in the joint analysis. However, there does seem to be significant differences in the station magnitude effects for underground explosions at the two islands possibly due to variations in the near source effects (Douglas et al [12]). Because of these possible differences in station magnitude effects it seems sensible to analyse the amplitude data for underground explosions at each island separately. Also near-source effects for atmospheric explosions may be less variable than for underground explosions and may generate signals with low predominant frequencies. For these reasons the data from the atmospheric explosions has been analysed separately from those of the underground explosions.

Now, the station network for each of the three analyses is not constant and it is possible that this will result in systematic biases in the magnitudes estimated. There is no sure way of correcting for these possible biases. Here, we have simply assumed that the average station effect for the analysis that uses the largest number of stations (that of the Mururoa underground explosions with 68 explosions and 178 stations) sets the baseline. Then for the Fangataufa underground explosions the average $s_{j}^{\mathrm{F}}-\mathrm{s}_{\mathrm{j}}^{\mathrm{M}}$ is computed; where $\mathrm{s}_{\mathrm{j}}^{\mathrm{F}} \quad$ is the magnitude term for station j obtained from the analysis of the observations from the Fangataufa explosions and $s_{j}^{M}$ the equivalent terms obtained from the analysis of the Mururoa observations; the average being formed from only those stations common to both the Fangataufa and Mururoa analyses. The average ( 0.043 magnitude units) is then subtracted from $s_{j}^{F}$ and added to the magnitudes of the Fangataufa explosions. The magnitudes and station terms for the atmospheric explosions have been corrected in a similar way. For these explosions 0.039 magnitude units have been subtracted from the magnitudes and the same value added to the station terms.

The data used for each analysis are: (i) Mururoa underground explosions - 1860 amplitude readings from 68 explosions and 178 stations; (ii) Fangataufa explosions - 99 readings from 3 explosions and 54 stations; (iii) atmospheric explosions- 55 readings from 5 explosions at 26 stations. The estimated magnitudes and station magnitude terms, corrected to a common baseline as
described above, are given in tables 1 and 2 respectively. For the station magnitude terms positive values indicate above average amplitudes and negative values those with below average amplitudes.

Comparisons of station terms from the various analyses are displayed in figure 2. Figure 2(a) shows a comparison of the station magnitude terms with the time terms. Assuming that $\mathbf{P}$ wave speeds in the earth are negatively correlated with attenuation - the lower the wave speed the greater the attenuation - then this would be expected to show up as a negative correlation between the station magnitude and time terms. As figure 2(a) shows, if there is such a correlation it is weak Figures 2(b) and 2(c) show respectively the station magnitude term for the Fangataufa underground explosions and the atmospheric explosions against the terms for the Mururoa underground explosions. It is clear that there is little correlation between the station magnitude terms which justifies the decision to analyse the three data sets separately.

The magnitude analyses described above were made using the distance-correction curve $(B(\Delta))$ of Lilwall [13] which covers the range $20-180^{\circ}$. The advantage of using this curve, particularly for the Tuamotu explosions is that observations from many more stations can be included than with the standard Gutenberg curve which ends at $100^{\circ}$. However, comparison of magnitudes ( $\mathrm{m}_{\mathrm{b}}^{\mathrm{ML}}$ ) estimated using the data from $20-180^{\circ}$ range with those estimated using data in the $20-100^{\circ}$ range shows that with the larger range the magnitudes are 0.09 magnitude units larger than those obtained with stations only out to $100^{\circ}$ (figure 3(a)). Conversely the station magnitude terms obtained using data at distances of $100^{\circ}$ and less are 0.09 magnitude units larger than those obtained using data out to $180^{\circ}$ (figure 2(d)). (Similar results are obtained using the Gutenberg curve to estimate the magnitudes for data in the $20-100^{\circ}$ range.) This result may indicate that the $\mathrm{B}(\Delta)$ curve of Lilwall is systematically too large at distances beyond $100^{\circ}$. Alternatively it may be that the amplitudes observed on ray paths between the Mururoa test site and stations at PKP distances are systematically above the world average. This remains to be investigated. Perhaps surprisingly however, comparison of the $\mathrm{m}_{\mathrm{b}}^{\mathrm{ML}}$ obtained here and those published by the ISC (which uses the Gutenberg curve) shows that any systematic difference between the two sets of magnitudes is small (figure 3(b)). As expected what differences there are, are greatest ( $\approx 0.1$ magnitude units) at the lowest magnitudes and these differences decrease as magnitude increases. Above about $m_{b} 5.5$ the differences are negligible.

## 4. ACKNOWLEDGEMENTS

The authors wish to thank the analysts around the world who measure and report Pwave amplitudes to the ISC. Without these amplitudes this report could not have been written.

＂$N_{1}$ is the number of arrival times used to estimate the time term．
$N_{1}, N_{2}$ and $N_{3}$ are the number of amplitude observations used to estimate the amplitude terms．

## FIGURE 1. MAPS OF MURUROA AND FANGATAUFA AND ESTIMATED EPICENTRES.

a) ISC epicentres.
b) JED epicentres computed using data for all 76 explosions.
c) JED epicentres computed using only data for the 5 Fangataufa explosions.

## FIGURE 2. COMPARISONS OF STATION TERMS

a) Station Magnitude terms against station time-terms for the Mururoa underground explosions.
b) Station magnitude terms for the Fangataufa underground explosions against the magnitude terms for the Mururoa explosions.
c) Station magnitude terms for the atmospheric explosions against the the magnitude terms for the Mururoa underground explosions.
d) Station magnitude terms for the Mururoa underground explosions derived using only data in the range $20-100^{\circ}$ against those derived using only data out to $180^{\circ}$.

## FIGURE 3.

a) Maximum-likelihood magnitudes derived for the Mururoa underground explosions using only data in the range $20-100^{\circ}$ against the magnitudes derived using the data in the range $20-180$.
b) ISC magnitudes against maximum-likelihood magnitudes. Also shown is the line $m_{b}{ }^{\text {ISC }}=m_{b}{ }^{\mathrm{ML}}$ and the least squares line through the data.
